The next edition of ASCE 7 Minimum Design Loads for Buildings and Other Structures, ASCE 7-16 (ASCE, 2016), is expected to be published in September 2016, in time for adoption into the 2018 International Building Code (IBC) (ICC, 2018). For that edition, ASCE 7-10 (ASCE, 2010) has been modified to include a new Section 12.10.3, Alternative Design Provisions for Diaphragms including Chords and Collectors, within Section 12.10, Diaphragms Chords and Collectors. The new section provides for an alternative determination of diaphragm design force level, which is mandatory for precast concrete diaphragms in buildings assigned to SDC C, D, E, or F. The alternative is permitted to be used for other precast concrete diaphragms, cast-in-place concrete diaphragms, and wood sheathed diaphragms on wood framing. Section 12.10.3 does not apply to steel deck diaphragms. ASCE 7-10 has also been modified to add a Section 14.2.4, containing detailed design provisions for precast concrete diaphragms including a connector qualification protocol. Chapter 14 of ASCE 7-10 is currently not adopted by the 2012 or 2015 IBC (ICC, 2012, 2015). Steps directed towards the inclusion of ASCE 7-16 Section 14.2.4 in the 2018 IBC are now being taken.

Both changes originated in the 2015 NEHRP Recommended Provisions for Buildings and Other Structures (FEMA, 2015). This article is devoted to a discussion of ASCE 7-16 Section 12.10.3, Alternative Design Provisions for Diaphragms including Chords and Collectors.

**Basis and Overview**

The seismic design of structures has long been based on an approximation of the inelastic response of the seismic force-resisting system. The approximation reduces the results of an elastic analysis in consideration of the reserve strength, ductility, and energy dissipation inherent in the vertical elements of the seismic force-resisting system. In 1978, ATC-3 (ATC, 1978) provided design force reduction factors based on consideration of inelastic behavior of the vertical elements of the seismic force-resisting system and the performance of structures in past earthquakes. The primary assumption leading to these factors is that yielding in the vertical elements of the seismic force-resisting system is the primary mechanism for inelastic behavior and energy dissipation. Starting with the 1997 Uniform Building Code (UBC) (ICBO, 1997), the actual forces and displacements that might occur in the vertical elements in a design-level seismic event were recognized with the introduction of a seismic force amplification factors, $\Omega_0$, and deflection amplification factor, $C_d$, respectively. In contrast, the design requirements for the horizontal elements of the lateral force-resisting system (the diaphragms) have been established by empirical considerations related to anticipated behavior of the vertical elements, rather than explicitly considering behavior of the diaphragms. For established diaphragm construction types, this empirical approach has been generally satisfactory. Satisfactory system performance, however, requires that the diaphragms have sufficient strength and ductility to mobilize the inelastic behavior of the vertical elements.

In order to help achieve the intended seismic performance of structures, the designs of horizontal and vertical elements of the seismic force-resisting system need to be made more consistent. Analytical results, as well as experimental results from shake-table tests in Japan, Mexico, and the United States, have shown that diaphragm forces over much of the height of the structure actually experienced in the design-level earthquake may at times be significantly greater than code-level diaphragm design forces, particularly where diaphragm response is near-elastic. Overstrength and ductility of the diaphragm, however, may account for satisfactory diaphragm performance. ASCE 7-16 Section 12.10.3 ties the design of diaphragms to levels of force and deformation capacity that represent actual anticipated behavior.

ASCE 7-16 Section 12.10.3 presents a near-elastic diaphragm force as the statistical sum of first mode effect and higher mode effects (Rodriguez et al., 2002). The first mode effect is reduced by the $R$-factor of the seismic force-resisting system, but then amplified by the overstrength factor, $\Omega_0$, because vertical element overstrength will generate higher first mode forces in the diaphragm. The effect caused by higher mode response is not reduced. In recognition of the deformation capacity and overstrength of the diaphragm, the elastic diaphragm force from the first and higher modes of response is then reduced by a diaphragm force reduction factor, $R$. With the modification by $R$, the proposed design force level may not be significantly different from the diaphragm design force level of ASCE 7-16 Sections 12.10.1 and 12.10.2 for many practical cases. For some types of diaphragms and for some locations within structures, the proposed diaphragm design forces will change significantly, resulting in noticeable changes to resulting construction. Based on data from testing and analysis, and on building performance observations, it is believed that these changes are warranted.

The alternative design force level of Section 12.10.3 is based on work by Rodriguez, Restrepo, and Carr (Rodriguez et al., 2002), verified by more recent work by Fleischman et al. (Pankow, 2014).
The latter buildings are treated in FEMA P-1026 (FEMA, 2015a). The alternative diaphragm design force level is given in Equations 2 and 3.

$$F_{px} = \frac{\sum F_i}{\sum w_i} \leq 0.4 \times 0.2 \lesssim w_{px} \lesssim 0.4 \lesssim w_{px}$$

where:

- $F_{px}$ is the diaphragm design force at Level $x$.
- $F_i$ is the portion of the seismic base shear, $V$, induced at Level $i$.
- $w_i$ is the weight tributary to Level $i$.
- $w_{px}$ is the weight tributary to the diaphragm at Level $x$.
- $S_{Dx}$ is the design spectral response acceleration parameter at short periods.
- $I$ is the seismic importance factor.

This empirical seismic design force level has generally resulted in satisfactory performance of diaphragms in earthquakes, as evidenced by a lack of observed severe damage. Material-specific factors related to diaphragm over-strength and deformation capacity may account for the adequate performance.

Results using analysis tools not available when the empirical rules were first established, indicate that the level of force required for design of diaphragms in new code-compliant buildings may not ensure development of inelastic mechanisms in the vertical elements of the seismic force-resisting system. This is particularly true where diaphragms have limited ductility and displacement capacity, as dramatically illustrated by the response of several shear wall structures during the Northridge Earthquake.

**Alternative Diaphragm Seismic Design Force Level**

The alternative diaphragm seismic design force level is for buildings in which response of the vertical elements of the seismic force-resisting system dominates the overall structure behavior. It is not meant for buildings in which the seismic response is dominated by the diaphragms (as can occur in big-box buildings with flexible diaphragms). The latter buildings are treated in FEMA P-1026 (FEMA, 2015a).

$^1$ EDO is precast concrete diaphragm Elastic Design Option.
$^2$ BDO is precast concrete diaphragm Basic Design Option.
$^3$ RDO is precast concrete diaphragm Reduced Design Option.
$^4$ Elastic, basic, and reduced design options are defined in ASCE 7-16 Section 14.2.4.

**Current Diaphragm Seismic Design Force Level**

Current seismic design forces for diaphragms in ASCE 7-10, to be retained in ASCE 7-16, are a function of the design forces acting on the vertical elements and are, therefore, reduced by the $R$-factor that applies to the vertical elements. Upper- and Lower-bound limits on the forces are added, as shown in **Equation 1**.

$$F_{px} = \frac{\sum F_i}{\sum w_i} \leq 0.4 \times 0.2 \lesssim w_{px} \lesssim 0.4 \lesssim w_{px}$$

where:

- $F_{px}$ is the diaphragm design force at Level $x$.
- $F_i$ is the portion of the seismic base shear, $V$, induced at Level $i$.
- $w_i$ is the weight tributary to Level $i$.
- $w_{px}$ is the weight tributary to the diaphragm at Level $x$.
- $S_{Dx}$ is the design spectral response acceleration parameter at short periods.
- $I$ is the seismic importance factor.
Elastic Design Option (EDO): An option where elastic diaphragm response in the maximum considered earthquake is targeted.

Reduced Design Option (RDO): An option that permits limited diaphragm yielding in the design earthquake.

Distribution of Diaphragm Design Force along Height

As per Equation 2, the distribution of diaphragm design forces over the height of the structure varies as a function of $C_{pxi}$. For structures of three or more stories, $C_{pxi}$ varies linearly between $C_{p0}$ at the base and $C_{pi}$ at 80% of structural height, $h_n$, above the base. It then varies linearly between $C_{pi}$ at 0.8$h_n$ to $C_{pn}$ at $h_n$, as shown on the right hand portion of Figure 1. For one and two stories, $C_{pxi}$ varies between $C_{p0}$ and $C_{pn}$, as shown in the left hand portion of Figure 1.

In order to determine $C_{pxi}$ it is necessary to first determine $C_{p0}$, $C_{pi}$, and $C_{pn}$.

$C_{p0} = 0.4SDS_{20}Iw_{px}$ \hspace{1cm} \text{Equation 4}

$C_{pxi}$ is the greater of values given by:

$C_{pxi} = C_{p0}$ \hspace{1cm} \text{Equation 5}

$C_{pxi} = 0.9\Gamma_{m1}\Omega_0 C_s \hspace{1cm} \text{Equation 6}$

where:

$\Gamma_{m1}$ is first mode contribution factor

$\Gamma_{m1} = 1 + 0.5z_s(1 - \frac{1}{N}) \hspace{1cm} \text{Equation 7}$

$z_s$ = modal contribution coefficient modifier dependent on seismic force-resisting system, as given in Table 2.

$C_{pxi} = \sqrt{(\Gamma_{m1}\Omega_0 C_s)^2 + (\Gamma_{m2}C_s^2)^2} \geq C_{pxi} \hspace{1cm} \text{Equation 8}$

where:

$\Gamma_{m2}$ is higher mode contribution factor

$\Gamma_{m2} = 0.9z_s\left(1 - \frac{1}{N}\right)^2 \hspace{1cm} \text{Equation 9}$

$C_s$ is higher mode seismic response coefficient. $C_s$ is the smallest of values given by

$C_s = (0.15N + 0.25)I_{SDS} \hspace{1cm} \text{Equation 10}$

$C_s = I_{SDS} \hspace{1cm} \text{Equation 11}$

$C_s = \frac{L_{SDS}}{0.03(N-1)}$ \hspace{1cm} \text{For } N \geq 2 \hspace{1cm} \text{Equation 12}$

$C_s = 0$ \hspace{1cm} \text{For } N = 1 \hspace{1cm} \text{Equation 13}$

Validation

To validate the alternative seismic design force level, coefficients $C_{px}$ were calculated for various buildings tested on a shake table. Figures 2 and 3 plot the floor acceleration envelopes.
and the floor accelerations predicted from Equations 2 and 3 with $R_s = 1$ for two buildings built at full-scale and tested on a shake table (Panagiotou et al., 2011; Chen et al., 2013). $C_{po}$ is defined as the diaphragm design acceleration coefficient at the structure base, and $C_{px}$ is defined as the diaphragm design acceleration coefficient at Level $x$. The vertical distribution of measured floor accelerations is reasonably predicted by Equations 2 and 3. Research work by Choi et al. (2008) concluded that buckling-restrained braced frames are very effective in limiting floor accelerations in buildings arising from higher-mode effects. This finding is reflected in the provisions of ASE 7-16 Section 12.10.3, where the mode shape factor $x$ has been made the smallest for buckling-restrained braced frame systems. Figure 4 compares vertical distributions of average floor accelerations obtained from the nonlinear time-history analysis of four buildings (two steel buckling-restrained braced frame systems and two steel special moment frame systems) when subjected to an ensemble of spectrum-compatible earthquakes with floor accelerations computed from Equations 2 and 3, normalized to accelerations at the structure base. The proposed design equations predict the vertical distribution of accelerations in both the uppermost part of the building and in the lowest levels reasonably well.

Comparisons of Design Force Levels

Comparisons of diaphragm seismic design force levels along the heights of a number of buildings of various materials and assigned to various SDCs have been made. A few representative cases are shown below. For more comparisons, see FEMA P-1051 (FEMA, 2016).

4-Story Perimeter Wall Precast Concrete Parking Structure in Knoxville, TN

The structure for this example is a 4-story perimeter shear wall precast concrete parking garage. The lateral force-resisting system (LFRS) in the transverse direction is composed of four perimeter precast walls, two at each end of the structure. The LFRS in the longitudinal direction consists of interior lite walls flanking the central ramp. The SDC is C.

The comparison of diaphragm design force levels for the structure by ASCE 7-16 Sections 12.10.1 and 12.10.2 (marked ASCE 7), by ASCE 7-16 Section 12.10.3 (marked ASCE 7 Alt.), and by the 2015 NEHRP Provisions (labeled NEHRP), are illustrated in Figure 5 (page 22). EDO, BDO, and RDO in the figure stand for Elastic, Basic, and Reduced Design Options, respectively. A few changes were made to alternative design force level provisions of the 2015 NEHRP Provisions before they were adopted into ASCE 7-16. Those differences are not important for the purposes of this brief article.

Steel-Framed Office Structure in Seattle, WA

The structure for this example is a 12-story buckling-restrained braced frame office building in Seattle, WA. The SDC is D.

The comparison of diaphragm design force levels for the structure by ASCE 7-16 Sections 12.10.1 and 12.10.2 (marked ASCE 7), by ASCE 7-16 Section 12.10.3 (marked ASCE 7 Alt.), and by the 2015 NEHRP Provisions (labeled NEHRP), are illustrated in Figure 6 (page 22). All three sets of requirements produce the same diaphragm design forces through most of the height of the structure, because the minimum diaphragm design force controls, except that ASCE 7-16 Sections 12.10.1 and 12.10.2 produce slightly higher than minimum diaphragm design forces at and near the very top.

Figure 3. Comparison of measured floor accelerations and accelerations predicted by Equations 2 and 3 for a 5-story special MRF building (Chen et al., 2013).

Figure 4. Comparison of measured floor accelerations with accelerations predicted by Equations 2 and 3 for steel BRBF and special MRF buildings (adapted from Choi et al., 2008).
The structure for this example is a 15-story reinforced concrete special shear wall residential structure in northern California. The SDC is D.

The comparison of diaphragm design force levels for the structure by ASCE 7-16 Sections 12.10.1 and 12.10.2 (marked ASCE 7), by ASCE 7-16 Section 12.10.3 (marked ASCE 7 Alt., and by the 2015 NEHRP Provisions (labeled NEHRP), are illustrated in Figure 7. There is very little difference between the design force levels by ASCE 7-16 Section 12.10.3 and the Provisions. These force levels are higher than those given by ASCE 7-10 Sections 12.10.1 and 12.10.2 – throughout the building height for shear-controlled diaphragms and only near the top for flexure-controlled diaphragms.

The alternative diaphragm seismic design force level of ASCE 7-16, mandated for precast concrete diaphragms in buildings assigned to SDC C and above and permitted for other precast concrete diaphragms, cast-in-place concrete diaphragms, and wood sheathed diaphragms on wood framing, departs from the current empirical approach and brings the design forces closer to reality as indicated by observations, test results, and analytical results. The reader is encouraged to consult the 2015 NEHRP Provisions (FEMA, 2015) and commentary for more detailed discussion of the alternative procedure and development of the diaphragm force reduction factor $R_s$.

Acknowledgments
Kelly Cobeen, Jose Restrepo, and Mario Rodriguez contributed significantly to the research, understanding and codification of the material presented in this article. Their efforts, along with those of the other members of Issue Team 6 of the Provisions Update Committee of the Building Seismic Safety Council, originators of the alternative diaphragm design force level, are gratefully acknowledged.
